**Abstract.** As many large metropolitan areas have pledged for a rapid decrease of their greenhouse gas emissions through ambitious climate mitigation policies, the need for rapid and robust quantification methods became more pressing. At the global scale, the scarcity of satellite carbon dioxide (CO<sub>2</sub>) observations remains the major roadblock to producing independent city-scale CO<sub>2</sub> emissions estimates from atmospheric data, except for a handful of cities benefiting from a dense network of ground-based CO<sub>2</sub> sensors. In this study, we quantify the potential of assimilating indirect measurements from spaceborne sensors (here nitrogen dioxide - NO<sub>2</sub>) to constrain fossil fuel CO<sub>2</sub> emissions, relying on the co-emission of these two species during combustion. We developed a modeling framework using a NO<sub>x</sub>-aerosol chemistry transport model (WRF-Chem) and performed simulations of NO<sub>2</sub> and CO<sub>2</sub> over the Middle-East, an area known for its large cities, its frequent clear sky conditions and a fairly constant albedo from its desertic land. We first demonstrate the importance of production/destruction processes impacting NO<sub>2</sub> lifetime at short and long distances from the source, suggesting that simplified approaches may be impacted by large errors. In comparison to TROPOMI satellite observations, the simulated NO<sub>2</sub> plumes from emissions inventories (EDGAR) revealed large misattribution of NO<sub>2</sub> emissions at fine scales, hence an uncertain disaggregation of national emissions to single point sources in the industrial and energy sectors in the EDGAR inventory. We further studied the relationship between NO<sub>2</sub> and CO<sub>2</sub> during summer and winter seasons by simulating the enhancement ratios ( $\delta\text{NO}_2:\delta\text{XCO}_2$ ) in plumes produced by cities and point sources We found that the enhancement ratios are consistent with the observed ratios derived from the ESA TROPOMI (NO<sub>2</sub>) and NASA OCO-3 missions (XCO<sub>2</sub>). We conclude here that the spatial misattribution of NO<sub>2</sub> emissions parallels the misattribution of CO<sub>2</sub> emissions, and that improved NO<sub>2</sub> inventories could therefore be used to

20  
25  
30

improve the monitoring of CO<sub>2</sub> emissions at sub-national scales in current global inventories when a sufficiently-large amount  
35 of NO<sub>2</sub> satellite measurements are available.

## 1 Introduction

The increase in global fossil fuel emissions reached about 1 % in 2022 with large variations at the regional level (Friedlingstein et al., 2022). The two most commonly used approaches for estimating fossil fuel emissions are inventories (bottom-up) and atmospheric inversions (top-down; Enting et al., 1998). While inventories remain the primary source of information at national  
40 scale (Smith et al, 2022), inverse modeling techniques have increasingly informed policy makers and governments of unreported sources and natural sinks across the globe (Yu et al, 2023). Because bottom-up approaches rely on uncertain emission factors and activity data across various sectors of the economy, large errors and uncertainties have been documented at regional and local scales for CO<sub>2</sub> (Andres et al. 1996; Oda et al., 2019) but also for CO and NO<sub>x</sub> (Elguindi et al, 2020). Commonly used bottom-up emission inventories such as the Emissions Dataset for Global Atmospheric Research (EDGAR;  
45 Janssens-Maenhout et al, 2015) including various gases such as NO<sub>x</sub>, CO<sub>2</sub> and VOC for the entire globe (Crippa et al, 2020), the Copernicus Atmosphere Monitoring Service regional scale (CAMS-REG) including various chemical species (Kuenen et al, 2021) or the Open-Data Inventory for Anthropogenic Carbon dioxide (ODIAC) providing globally CO<sub>2</sub> emissions from fossil fuel combustions (Oda and Maksyutov, 2011) have provided gridded emissions estimates that can be combined with ground-based or satellite atmospheric measurements of greenhouse gases to perform atmospheric inversions (Lauvaux et al.  
50 2016; Staufer et al. 2016; Yadav et al., 2021). But the limited number of atmospheric station networks continuously measuring GHG concentrations limits our ability to perform atmospheric inversions over most regions of the globe (Peylin et al, 2013). Even satellite missions measuring CO<sub>2</sub> concentrations such as the NASA Orbiting Carbon Observatory (OCO-2; Crisp et al., 2017) or the JAXA GOSAT mission (Yokota et al., 2009) only collect a sparse and infrequent set of measurements at sub-national scales (Chevallier et al, 2017). The NASA Orbiting Carbon Observatory-3 (OCO-3) (O'Dell et al, 2018; Taylor et al,  
55 2023) mission offers a Snapshot Aera Mode (SAM) capturing partial images of XCO<sub>2</sub> concentrations few times a year over a selection of large cities and power plants across the world. However, most inverse studies assimilating OCO-3 measurements have not been able to monitor and to assess urban-scale emissions at policy-relevant scales (e.g. Ye et al., 2020; Kiel et al., 2021; Roten et al., 2022).

Since its launch in 2017, the Tropospheric Monitoring Instruments (TROPOMI) provides daily images of tropospheric NO<sub>2</sub>  
60 column measurements over the entire globe, part of the European Union's Copernicus Sentinel 5 Precursor (S5p) satellite mission (Copernicus Sentinel-5p, 2021) at 5 to 7 km resolution. Co-emitted during the combustion process of fossil fuel energy, NO<sub>2</sub> and CO<sub>2</sub> have been jointly studied to quantify fossil fuel emissions of CO<sub>2</sub> at fine scales (e.g. Hakkarainen et al, 2021; Kuhlman et al, 2020). The estimation of the NO<sub>2</sub>:CO<sub>2</sub> ratios remains uncertain, highly dependent on the activity sectors (Lei et al., 2022). Other studies have simply used NO<sub>2</sub> plumes from TROPOMI to assist in the detection of CO<sub>2</sub> plumes obscured  
65 by the high background CO<sub>2</sub> values (Reuter et al, 2019). The precise detection and quantification of NO<sub>x</sub> emissions from large

point sources has also been studied over multiple cities using Gaussian models to represent the atmospheric dispersion of pollutants (Wu et al, 2021). Yang et al (2023) have recently showcased a methodology to derive CO<sub>2</sub> emissions from NO<sub>2</sub> fields by using GEOS-Chem model, however they did not consider the chemical reactions in their methodology which could be a major issue for the correct simulation of NO<sub>2</sub> concentrations. The performance of atmospheric chemical models with regards to chemical and transport processes can lead to significant errors in emissions estimates (Stavrakou et al, 2013). The Weather Research and Forecasting (WRF) model (Skamarock and Klemp, 2008) coupled with its chemistry module (WRF-Chem, Grell et al, 2005; Fast et al, 2006) has been developed for studying atmospheric pollution, applied to top-down approaches (e.g. Georgiou et al, 2018) and coupled to bottom-up emissions estimates (Goldberg et al, 2019). The main advantage of utilizing an atmospheric model is the ability to simulate gas concentrations at high spatial and temporal resolutions while simulating the full complexity of chemical processes (e.g. Zhang et al, 2012; Sicard et al, 2021). From the comparison of the simulated NO<sub>2</sub> and CO<sub>2</sub> concentrations with satellite observations, it is possible to examine the emission inventories coupled to the atmospheric model for NO<sub>2</sub> (e.g. Luna et al, 2020) and for CO<sub>2</sub> (Kiel et al, 2021).

Regarding the complex NO<sub>x</sub> chemistry, NO to NO<sub>2</sub> concentrations rapidly vary depending on ozone (O<sub>3</sub>) concentrations and the presence of Volatile Organic Compounds (VOCs) that control OH radicals. Most combustion processes emit primarily NO molecules, converted into NO<sub>2</sub> within minutes after their release. Satellites only observe NO<sub>2</sub> columns, hence matching model simulations with satellite observations requires the use of a chemical transport model. The simulation of the conversion rate of NO to NO<sub>2</sub> (and inversely) remains highly uncertain due to nonlinear chemical processes, as described in Atkinson (2000) and Seinfeld and Pandis (2006). The most common pathway for the conversion of NO to NO<sub>2</sub> occurs via oxidation by ozone (O<sub>3</sub>). This conversion occurs on the order of tens of seconds to a few minutes and depends on the amount of available reactants, such as O<sub>3</sub> and VOCs, the intensity of solar radiation, as well as ambient meteorological conditions. However, during late afternoon and evening hours, high O<sub>3</sub> concentrations are observed in remote locations due to less titration by NO, and transport of O<sub>3</sub> and its precursors from their sources. At nighttime, without photolytic activity, and near very large emissions of NO (e.g. power plants), NO react with O<sub>3</sub> to form NO<sub>2</sub>, which subsequently produces nitric acid (HNO<sub>3</sub>) removed by wet and dry deposition (Monks et al., 2015). The complex chemistry of NO and NO<sub>2</sub>, and hence the relationship between CO<sub>2</sub> and NO<sub>2</sub>, requires the careful evaluation of the chemical transport model before using NO<sub>2</sub> concentrations to constrain CO<sub>2</sub> emissions. The aim of the current study is to address the ability to identify large NO<sub>2</sub> and CO<sub>2</sub> plumes over the Middle-East region by implementing the WRF-Chem model and comparing its outputs with satellite observations from TROPOMI and OCO-3 respectively, in the framework of the Eastern Mediterranean and Middle East - Climate and Atmosphere Research (EMME-CARE) project. The Middle East region is characterized by large emitters, an energy system based on fossil fuels, high energy consumption per capita, high-power demand due to high temperatures during the hot season and heavy industrial activities. Moreover, it is a region with an abundance of clear sky days throughout the year and a rather constant albedo which benefits satellite observations (Eskes et al, 2022). For the anthropogenic emissions inputs applied to the model, the EDGAR inventory was selected and provided data for the entire area of interest. Different emissions sectors were considered (from EDGAR) such as energy production, whose emissions come from large point sources (power plants), ground transportation, residential and

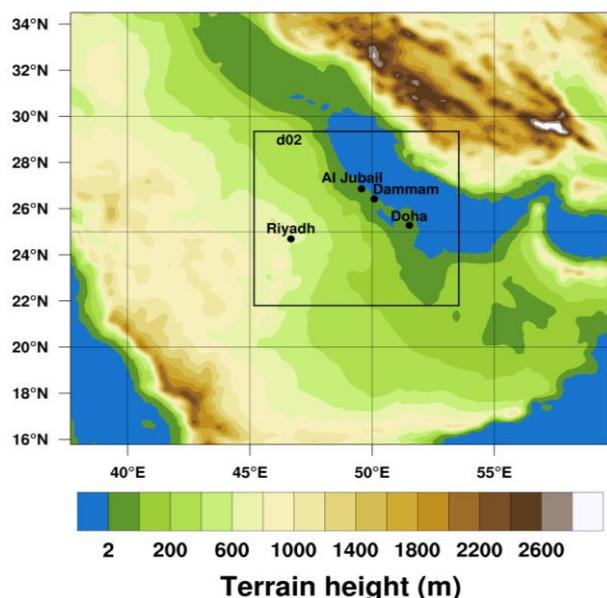

100 industries, all corresponding to different  $\text{NO}_2$ -to- $\text{CO}_2$  ratios. We examine the model performances in simulating the  $\text{NO}_2$ -to-  
NO (and vice-versa) conversion rates for individual plumes across the Middle East, before analyzing  $\text{NO}_2$ -to- $\text{CO}_2$  ratios and  
our ability to assimilate  $\text{NO}_2$  column measurements to estimate  $\text{CO}_2$  fossil fuel emissions. The methodology, WRF-Chem set-  
up and tools utilized for this study are presented in Section 2. Section 3 demonstrates the performances of WRF-Chem when  
simulating  $\text{NO}_x$ , with and without chemistry, along with the comparison between the model and satellite observations of the  
105  $\delta\text{NO}_2:\delta\text{XCO}_2$  enhancement ratios. Finally, Section 4 summarizes the key points of the study.

## 2 Methodology

### 2.1 WRF-Chem set up

The Weather Research and forecasting (WRF) model with chemistry module (WRF-Chem) version 3.9.1 (Skamarock and  
Klemp, 2008) was used for the simulation of the greenhouse gases over the Middle East region for the months of June and  
110 January 2021. Our study area encompasses several large cities including Riyadh, the capital and largest city of Saudi Arabia,  
Doha, capital and largest city of Qatar, and Dammam. The parent domain is about 2,000 km wide (139 by 139 grid points) at  
15 km spatial resolution, and the child domain (one-way nesting) is about 700 km wide (231 by 231 grid points) at 3 km spatial  
resolution, as shown in Fig. 1.

### WRF domain set up

115

Figure 1: WRF-Chem simulation domains at 15-km and 3-km resolutions, respectively, over the Middle-East and terrain height (in meter), using one-way nested mode.

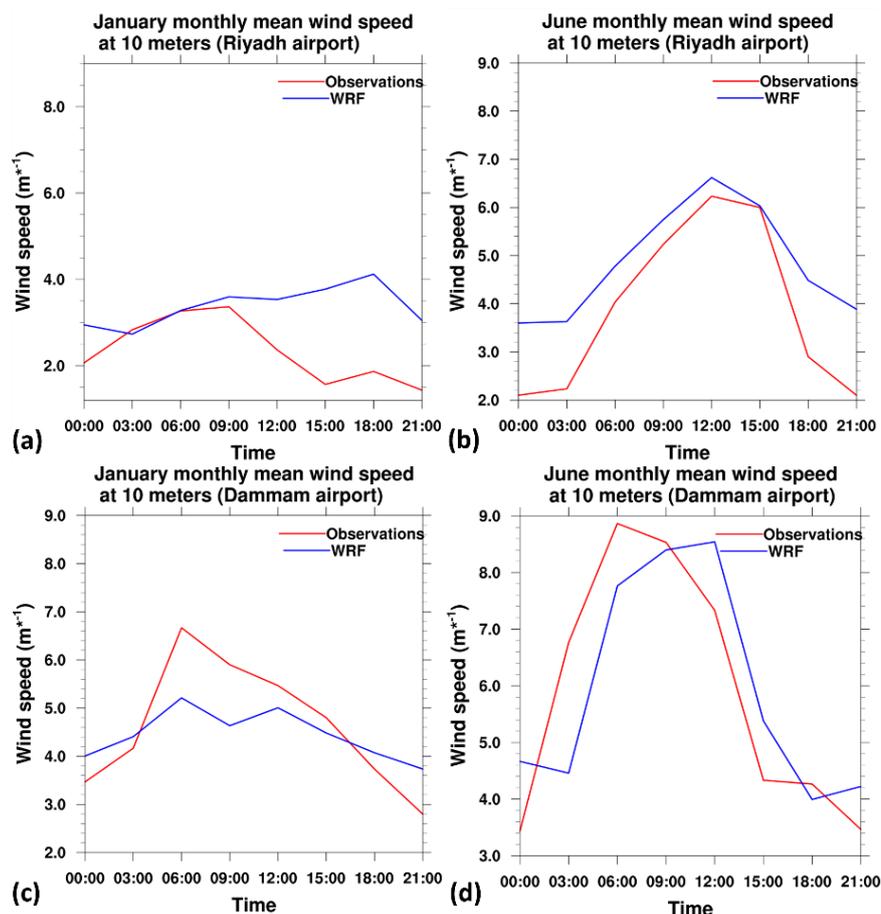

Regarding the WRF-Chem schemes options, we selected a configuration from previous studies of the atmospheric pollution  
 120 over the Middle East and the Eastern Mediterranean region (Zittis et al 2014; Georgiou et al, 2022). The atmospheric column  
 was represented by 33 vertical levels for both domains. The land surface energy exchange was simulated using the Noah Land-  
 Surface Model scheme (Chen and Dudhia, 2001), while the Planetary Boundary Layer dynamics was simulated using the  
 Yonsei University (YSU; Hong et al, 2006) planetary boundary scheme. For the chemistry scheme, the Carbon Bond  
 Mechanism version Z (CBM-Z, Zaveri and Peters, 1999) was preferred for its better performances in terms of NO<sub>x</sub>  
 125 concentrations (Visser et al, 2019) in combination with the Madronich TUV photolysis scheme (Madronich, 1987; Tie et al,  
 2003). The main schemes and options are described in Table 1.

**Table 1: The basic options for the WRF-Chem setup.**

For a simple model validation of wind fields, we compared the wind speed at 10 meters above ground level with the available  
 130 METAR observations (Iowa Environmental Mesonet) at the two operational stations of Riyadh and Dammam airports. As  
 shown in Fig. 2, monthly averages (January and June 2021), for January 2021, at the Riyadh airport station from 00:00 UTC  
 until 10:00 UTC agree within  $<1 \text{ m s}^{-1}$  when the wind speed ranges from  $2 \text{ m s}^{-1}$  to  $4 \text{ m s}^{-1}$ , while the WRF model overestimates  
 the wind speed by approximately  $2 \text{ m s}^{-1}$  from 12:00 UTC to 21:00 UTC, during low wind speed conditions. For June 2021,  
 the WRF model agrees with the observations for the period 06:00 UTC to 15:00 UTC within  $0.5 \text{ m s}^{-1}$ , while overestimating  
 135 wind speed for the time periods 00:00-03:00 UTC and 18:00-21:00 UTC, during low wind speed conditions. On the other  
 hand, at the Dammam airport station, the WRF model tends to underestimate wind speed during January 2021 for the time  
 period 06:00-12:00 UTC by approximately  $1\text{-}2 \text{ m s}^{-1}$ , and to overestimate wind speed at 00:00 and 21:00 UTC by  $1 \text{ m s}^{-1}$ .  
 During June 2021, the WRF model tends to underestimate wind speed at 03:00 and 06:00 UTC by  $1\text{-}2 \text{ m s}^{-1}$ , but overestimates  
 wind speed at 12:00, 15:00 and 21:00 UTC by approximately  $1 \text{ m s}^{-1}$ .

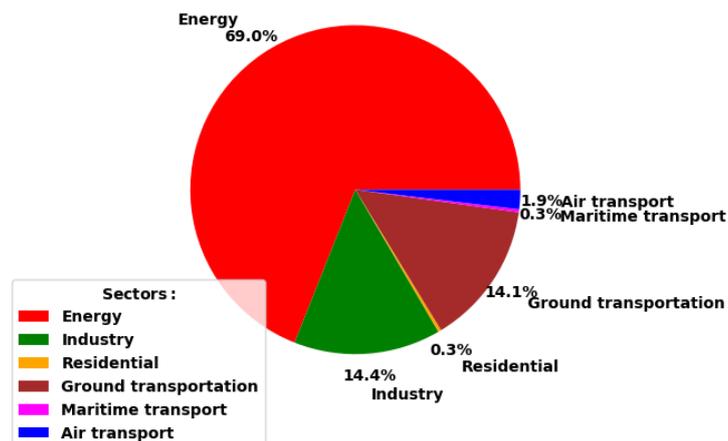

140

**Figure 2: Modeled and observed monthly mean wind speed (m/s) at 10 meters for the months of January (left column) and June (right column) 2021 over Riyadh (top row) and Dammam (bottom row) airports.**

The EDGAR-htap v2.2 emission dataset (Joint Research Centre Data Catalogue, 2017) was coupled to the WRF-Chem model to simulate the anthropogenic concentrations. It is important to note that the dataset providing all the necessary gases for the  
145  $NO_x$  simulation is based on 2010 data. Later versions of the EDGAR inventory, up to the time of the study, do not include important species required to simulate  $NO_x$ , most notably non-methane volatile organic compounds (NMVOCs) for the  $NO_x$  simulations. The EDGAR-htap v2.2 data are categorized in 5 different sectors: energy, industry, residential, and traffic, and air/shipping transportation (vehicles, airplanes and ships). Fig. 3 shows the contribution of each sector to the total  $NO_x$  emissions as a ratio of the sums of the  $NO_x$  emissions within the nested domain (Fig. 1) for each sector over the total sum of  
150 the emissions from all sectors. The energy sector is the main contributor to the  $NO_x$  emissions in the area for January and June 2010 with 69 % of the total, followed by the industry and ground transportation sectors (around 14 %). The air transportation contributes to 1.9 % of the total emissions, and the residential emissions to 0.3 %. Fig. 3 shows the results for January 2010, overall similar to June 2010.

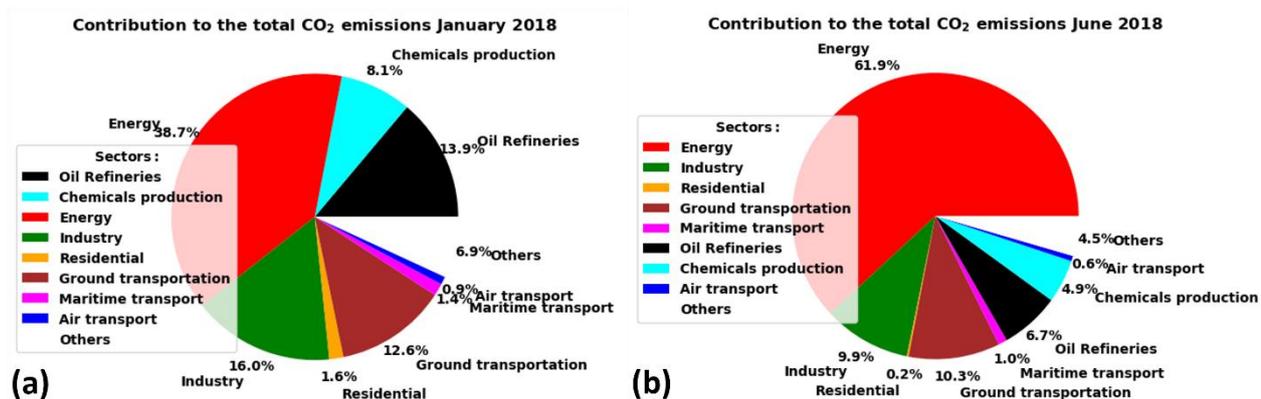

Contribution to the total NO<sub>x</sub> emissions January 2010

155 **Figure 3: Contribution of the different energy sectors to the total NO<sub>x</sub> emissions for the nested domain of the study (Fig. 1) based on the EDGAR emissions inventory for January 2010.**

Considering the CO<sub>2</sub> emissions, the EDGAR Greenhouse Gas Emissions (ghg) version 6.0 dataset of 2018 (Joint Research Centre Data Catalogue, 2021) was preferred (Monforti Ferrario et al., 2021). Because CO<sub>2</sub> is not reacting with other atmospheric species, we selected a later version to compare and to diagnose any changes in the point source locations compared to the EDGAR htap v2.2 dataset. In addition, the CO<sub>2</sub> EDGAR dataset consists of emissions from 18 sectors: energy, agriculture, industry, iron production, non-energy fuels, non-ferrous metals, non-metallic minerals, chemicals production, fossil fuel fires, fuel production, other products, residential, oil refineries, soil waste and transportation (vehicles, airplanes and ships). Fig. 4 displays the contribution of the different sectors to the total CO<sub>2</sub> emissions similarly to Fig. 3. However, the results show a strong seasonal variability in the energy sector contributing to 38.7 % of the total emissions, followed by the industry sector with 16 %, the oil refineries with 13.9 %, the ground transportation with 12.6 %, the chemicals production with 8.1 % and the rest of the sectors amounting to 10.4 % in January 2018. These results are quite different compared to June 2018, where the energy sector is contributing to 61.9 % of the total emissions, followed by the ground transportation sector with 10.3 %, the industry with 9.9 %, the oil refineries with 6.7 %, the chemicals production with 4.9% and the remaining sectors accounting for 6.3 %.

170

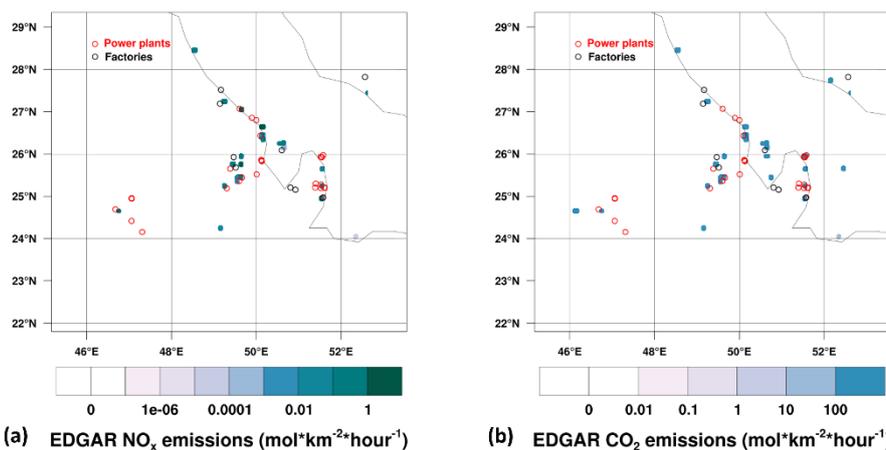

**Figure 4: Contribution of the different energy sectors to the total CO<sub>2</sub> emissions for the nested domain of the study (Fig. 1) based on the EDGAR emissions inventory for January and June 2018.**

The EDGAR datasets provide emissions for the general molecular form of the various species (e.g. NO<sub>x</sub>, Black Carbon, Organic compounds). Table A1 displays the relationships between the gas forms provided by EDGAR and how they should be converted into WRF-Chem emissions species before being coupled to the chemistry module according to the WRF-Chem 3.9.1.1. emissions guide (2018). A recent study from Rey Pommier et al (2023) has produced a detailed infrastructure map with the known locations of the power plants and factories over the Middle East region, with 62 emitting sites in total. We show in Fig. 5 the locations of power plants and factories over the EDGAR-htap v2.2 NO<sub>x</sub> and EDGAR-ghg v6.0 emissions maps from the energy sector to unveil possible deficiencies of the energy point sources in the EDGAR datasets for our nested domain. The EDGAR NO<sub>x</sub> emissions lack some of the point sources along the Saudi Arabian and the Qatari coastlines as well as near the city of Riyadh (cf. Fig. 5(a)).

175

180

**EDGAR NO<sub>x</sub> Energy emissions June 2010 with known sources locations**      **EDGAR CO<sub>2</sub> Energy emissions June 2018 with known sources locations**

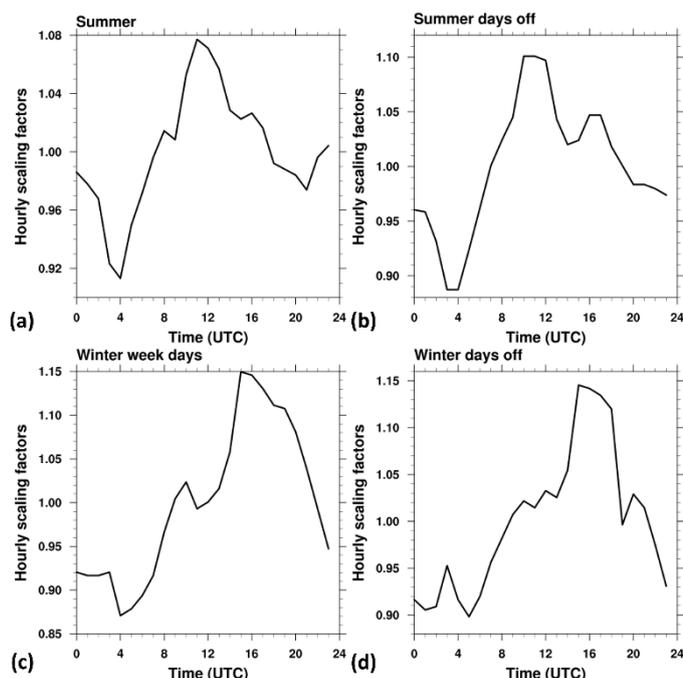

185

**Figure 5: EDGAR NO<sub>x</sub> monthly mean emissions for June 2010 (a) and CO<sub>2</sub> monthly mean emissions for June 2018 (b) solely for the energy sector along with the locations of the power plants and factories compiled (Rey Pommier et al, 2023) for the nested domain (Fig. 1). The power plants and factories with no values for EDGAR emissions reveal the missing sources of the inventory.**

190 Furthermore, the EDGAR datasets provide a mean diurnal profile of emissions for each month without considering the weekly and diurnal variability. Hence, we considered diurnal and weekly variations by estimating a scaling factor of EDGAR's profiles based on the energy consumption for Saudi Arabia, taking into account the seasonal variability as well as weekends (Friday and Saturday) (Al Ghamdi, 2020). We applied these scaling factors to generate hourly emissions over the region. The values for the scaling factor are presented in Fig. 6, with values ranging from 0.9 to 1.15, while weekly and seasonal cycles remain limited in peak-to-peak amplitude (0.2 to 0.3).

195 **Figure 6:** The hourly scaling factors for the parent and nested domains (Figure 1) in summer week days (a), summer days off including rest days on Fridays (b), winter week days (c) and winter days off (d) for January and June 2021, applied to the EDGAR emissions to include diurnal variability and estimated based on the electricity consumption in Saudi Arabia.

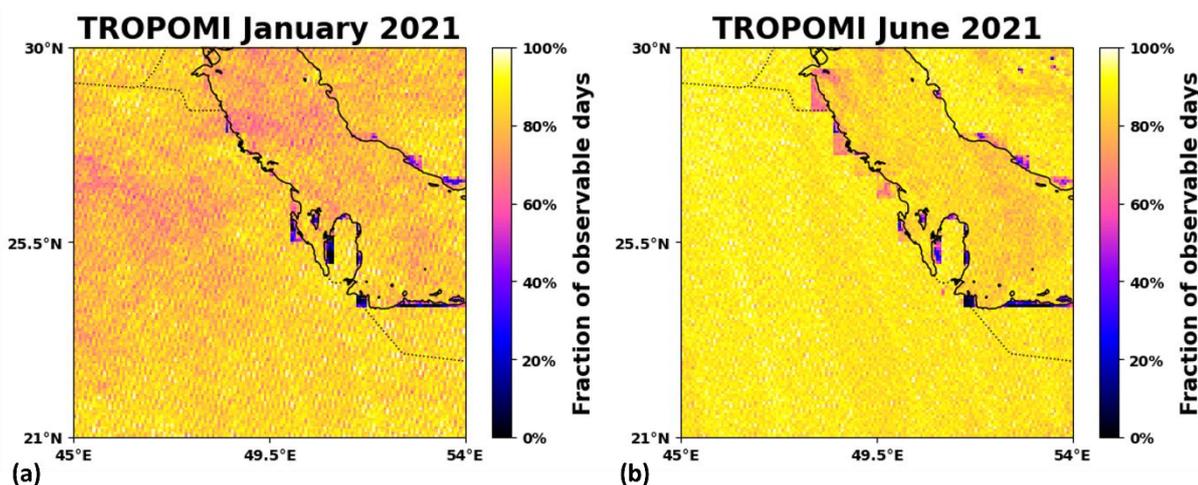

## 2.2 Satellite observations

200 The model outputs for January and July 2021 were compared against satellite observations. In particular, the simulated  $\delta\text{NO}_2$  (see Section 3.3) were compared against the TROPOMI observations and the simulated  $\delta\text{XCO}_2$  (see Section 3.3) against the NASA OCO-3  $\text{XCO}_2$  retrievals in SAM mode (see Fig. 10, 13, 14, 15). We collected a daily TROPOMI image sampled at approximately 10:00 UTC for the periods January 2021 and June 2021. The  $\text{NO}_2$  data were downloaded from the European Space Agency (ESA) for the European Union's Copernicus Sentinel 5 Precursor (S5p) satellite mission (Copernicus Sentinel-5p, 2021). We note here that potential biases in TROPOMI  $\text{NO}_2$  retrievals have been documented over large metropolitan areas Judd et al (2020). Regarding the evaluation of  $\delta\text{XCO}_2$ , we used the NASA OCO-3 observations from the NASA Goddard Earth Science Data and Information Services Center (GES 184 DISC) (<http://disc.sci.gsfc.nasa.gov/>). Only few partial images

205 with a sufficient number of quality-flagged retrievals (the retrievals cover the urban areas) are available over the region for the months of January and June 2021, mainly over the cities of Riyadh and Dammam. The full list of days collected by OCO3 are shown in Fig. A1.

Regarding the TROPOMI satellite data, Fig. 7 presents the fraction of days for each pixel where the quality factor is higher than 0.75. It is apparent that for June 2021, the fractions for the vast majority of the pixels are more than 80% with some exceptions near the Saudi Arabian coastline and the Qatar coastline where the fractions decrease to approximately 70%, down to 60% for some pixels. During January 2021 the fractions for most of the pixels range from 70% to 80%, with some pixels in Saudi Arabian coastline and the Qatar coastline dropping below 40%.

215 **Figure 7: Fractions of good quality ( $qa > 0.75$ ) TROPOMI observations for each grid point of the nested domain (Figure 1) for January 2021 (a) and June 2021 (b).**

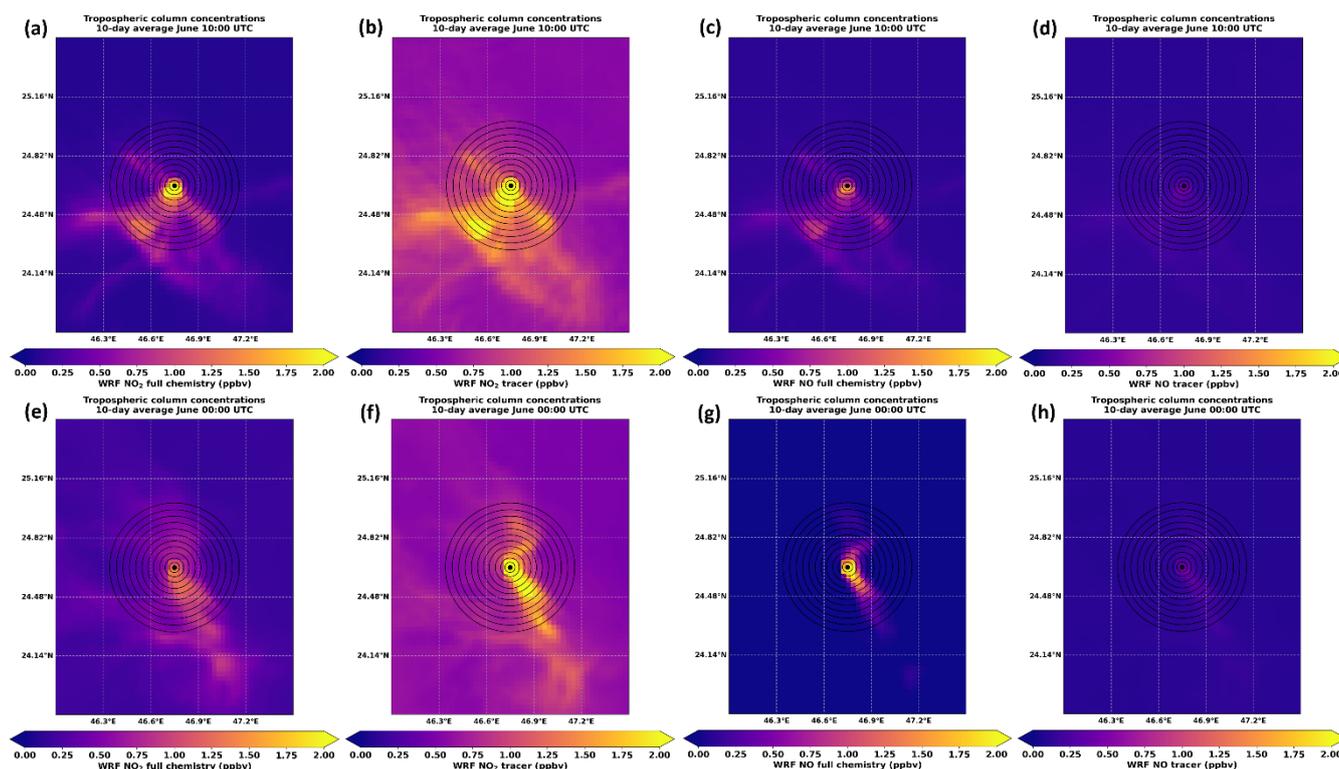

### 3. Results

#### 3.1 Impact of chemistry in WRF-Chem simulations

In order to evaluate the role of the chemical processes impacting  $\text{NO}_2$  (production/destruction rates, and  $\text{NO}$ -to- $\text{NO}_2$  conversion rate), we carried out WRF-Chem simulations without the chemistry module for the period 1 to 10 June 2021 ( $\text{NO}$  and  $\text{NO}_2$  were both considered as passive tracers). According to existing literature, the  $\text{NO}$ -to- $\text{NO}_2$  conversion that occurs via oxidation by ozone (e.g. Hanrahan, 1999; Atkinson 2000; Seinfeld and Pandis 2006) is often assumed to be instantaneous. We used the same model set-up as Section 2.1, however, for the passive tracer run, the EDGAR htap v2.2  $\text{NO}_x$  input emissions were distributed as 90 %  $\text{NO}_2$  and 10 %  $\text{NO}$ , contrary to the full chemistry run where  $\text{NO}_x$  was distributed as 90 %  $\text{NO}$  and 10 %  $\text{NO}_2$ . The partitioning in  $\text{NO}_x$  emissions in the full chemistry run has been used in several previous studies (e.g. Solazzo et al.,

2017; Visser et al, 2019), while the high fraction of  $\text{NO}_2$  in the no-chemistry run (90 %) has been used in recent studies to compensate for the absence of short-term conversion of  $\text{NO}$ -to- $\text{NO}_2$  (e. g. Kuhn et al, 2023; Xiang et al, 2022). We compared the variations of  $\text{NO}_2$  and  $\text{NO}$  concentrations as a function of the distance to an intense localized source, using both simulations (with and without chemistry), focusing on the isolated plume coming from the city of Riyadh. In Fig. 8, we show the sum of the  $\text{NO}_2$  concentrations over the tropospheric column depicted as the average of the 10-day period in June at 00:00 and 10:00 UTC (Fig. 8, panels a,b, e, and f). Similarly, we show the sum of the  $\text{NO}$  concentrations over the same area for the same period (Figures 8, panels c, d, g, and h). In the no-chemistry run, the  $\text{NO}_2$  plumes display higher concentrations and extend further spatially, especially near the source compared to the chemistry run. The background  $\text{NO}_2$  concentration is also higher in the no-chemistry run. Inversely,  $\text{NO}$  concentrations are higher in the full chemistry run compared to the no-chemistry simulation, due to their low assumed fraction in total  $\text{NO}_x$ .

**Figure 8: WRF-Chem simulated  $\text{NO}_2$  (a,b, e, f) &  $\text{NO}$  (c, d, g, h) tropospheric column concentrations averaged for the period 1-10 June 2021 at 00:00 & 10:00 UTC with the highlighted point source and the distances (rings) for the run with the full chemistry activated and the only tracers run.**

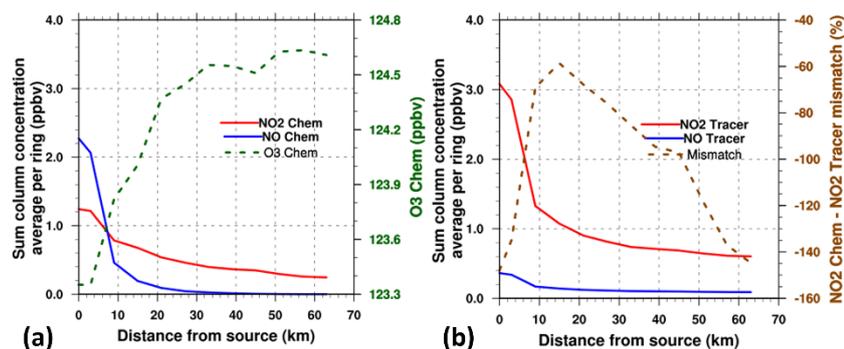

240 We show in Fig. 9 the sum of the concentrations within each ring (shown in Fig. 8) apart by 3 km, representing the evolution of both gases against the distance from the source. As shown in Fig. 8, the WRF-Chem model instantaneously converted  $\text{NO}$  to  $\text{NO}_2$  during daytime (low  $\text{NO}$  concentrations). For the full chemistry simulations, the  $\text{NO}_2$  and  $\text{NO}$  concentrations became almost null 40 km away from the point source due to the formation of  $\text{O}_3$ , whereas for the passive tracers simulation, the  $\text{NO}_2$

concentrations remain significant even 57 km away from the source leading to a 200 % mismatch between the two  
245 configurations. At night, the NO concentrations near the point source are higher when the chemistry is activated due to the  
lack of incoming radiation, reducing further the NO-to-NO<sub>2</sub> conversion rate. However, as the lifespan of NO is much shorter  
compared to NO<sub>2</sub>, we noticed that the NO<sub>2</sub> concentrations became higher than NO starting from 9 km away from the source.  
Next to the source (large emissions of NO and VOC), NO is converted to NO<sub>2</sub> to form O<sub>3</sub> in the presence of sunlight. Another  
important reaction is the titration of O<sub>3</sub> by NO to form NO<sub>2</sub>, which is converted to HNO<sub>3</sub>, later removed by wet and dry  
250 deposition processes. This reaction is especially important during the night when there is no photolytic reaction with NO<sub>2</sub>, and  
O<sub>3</sub> levels are the lowest as we can see near the point source in Fig. 9. However, as the plume moves further downwind, less  
NO is available to react with O<sub>3</sub>. Consequently, there is less O<sub>3</sub> degradation and O<sub>3</sub> levels increase as shown in Fig. 9. The  
mismatch (up to 300%) during daytime between NO<sub>2</sub> from full chemistry simulations and NO<sub>2</sub> modeled as a tracer (no  
chemistry) is mainly due to the formation of secondary pollutants (e.g. O<sub>3</sub>) in the full chemistry simulation, confirming that  
255 this reaction is clearly an important process when considering large point sources (e.g. power plants). The only sinks for the  
NO and NO<sub>2</sub> tracers are the deposition processes. The anticorrelation between O<sub>3</sub> and NO<sub>x</sub> for the Saudi Arabia region was  
also observed via in-situ measurements in the area during 2007 (Butenhoff et al, 2015). Lama et al. (2022) have simulated NO<sub>2</sub>  
as a tracer with the WRF-Chem model for the period June to October 2018 over the city of Riyadh. Their modeled average  
values of the tropospheric column concentrations for NO<sub>2</sub> at 10:00 UTC range from 1.4 to 0.4 ppbv, similar to the NO<sub>2</sub>  
260 concentration values we observed in our full chemistry simulation ranging from 2.2 ppbv above the source to 0.2 ppbv 60 km  
away from the source (cf. Fig. 9(c)).

### Riyadh 10-day average 00:00:00 (UTC)

### Riyadh 10-day average 10:00:00 (UTC)

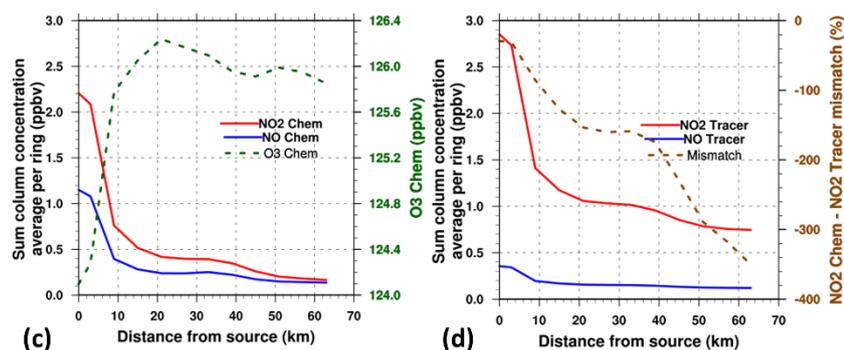

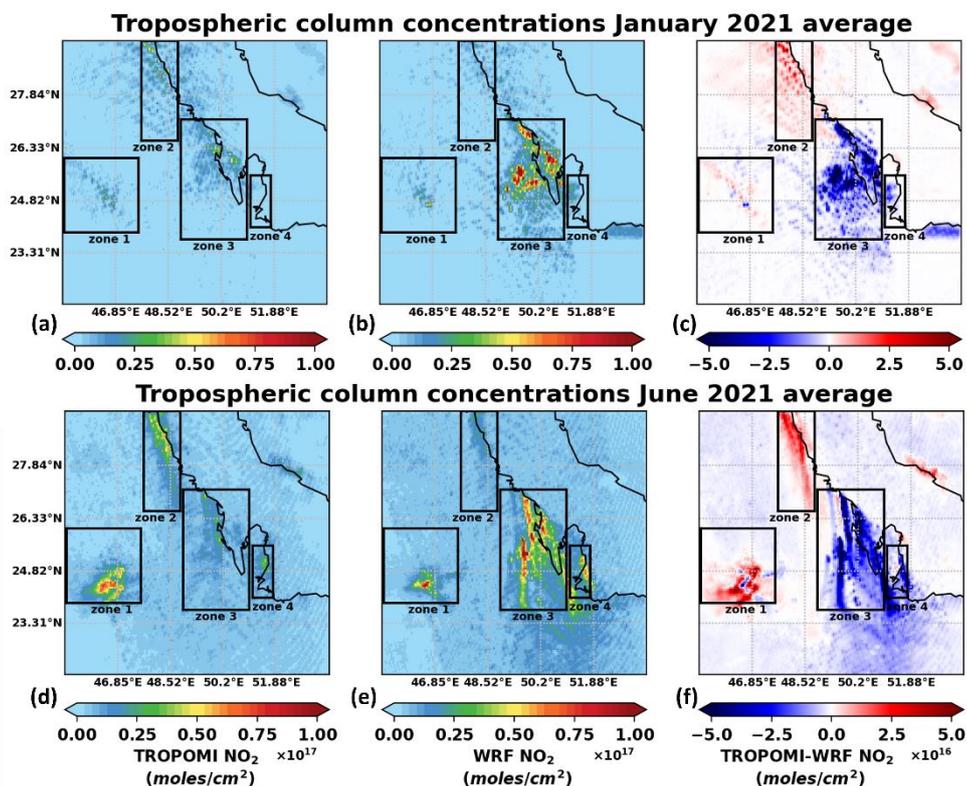

Figure 9: Comparison of 10-day average sum of the NO<sub>2</sub> and NO concentrations, including O<sub>3</sub> and the NO<sub>2</sub> mismatch between the full chemistry (left column) and the tracer (or no chemistry) run (right column), at 00:00 (a-b) and 10:00 (c-d) UTC in June as a function of distance from the source.

265

### 3.2 Comparison of satellite TROPOMI observations and WRF-Chem simulation

We compared the NO<sub>2</sub> tropospheric column concentrations from TROPOMI and from our WRF-Chem simulations using the full chemistry scheme for the months of January and June 2021 (cf. Fig. 10). More particularly, we compared the average value for the months of January and June 2021 at approximately 10:00 UTC for the nested domain of the simulation after regriding the WRF outputs to the TROPOMI observations and applying the same averaging kernel to the vertical levels. A Gaussian filter has also been applied in order to avoid some of the background noise (Goldberg et al, 2019; Goudar et al, 2023). During the month of January, the quality of the observations was frequently subpar, as seen in Fig. 7 but the overall coverage remains sufficient to evaluate the model-data mismatches over the entire month.

270

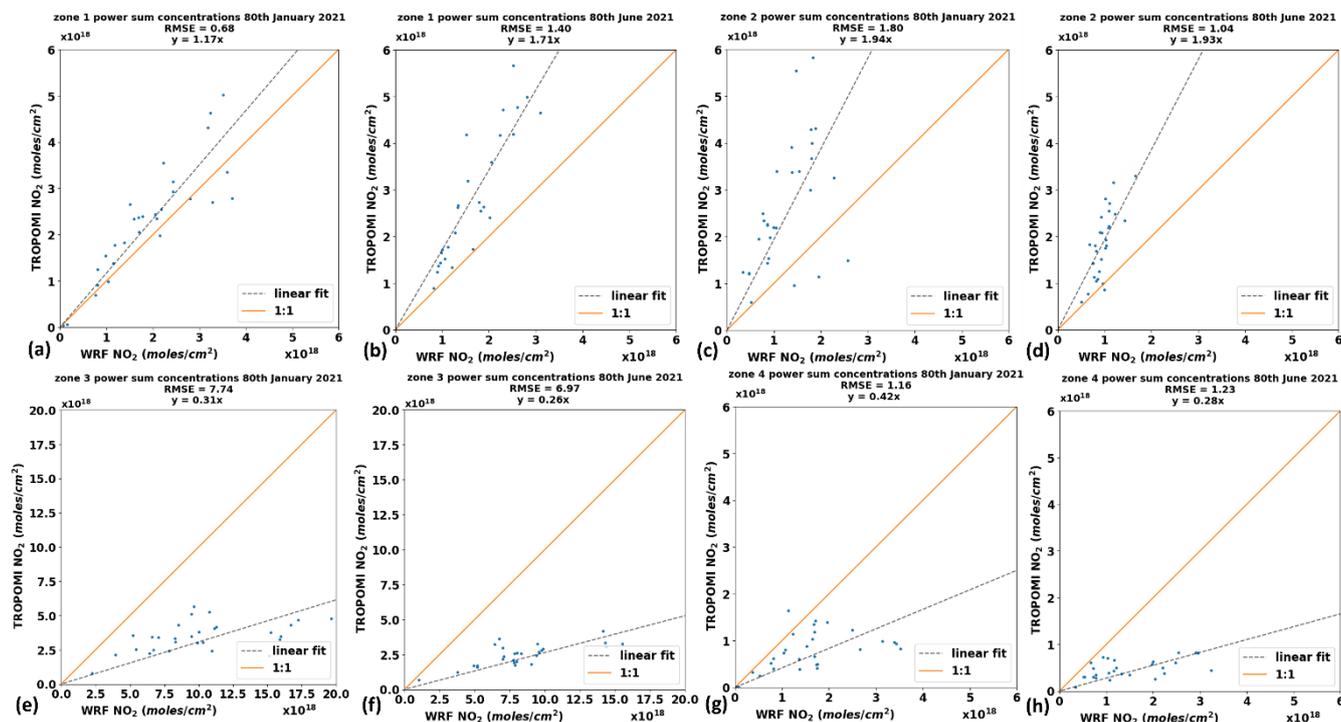

275 **Figure 10: Tropospheric column NO<sub>2</sub> concentrations for the TROPOMI observations and the WRF-Chem outputs, alongside their concentration difference, monthly average for January 2021 (a-b-c) and June 2021 (d-e-f) at 10:00 UTC.**

As we can see from Fig. 10, there is not a good agreement between the satellite data and the modeled concentrations regarding the location of the point sources (upwind of the plumes). Nevertheless, the sizes and intensity of the plumes of NO<sub>2</sub> vary across the different regions. Over the coastal capital city of Qatar, Doha (zone 4), the modeled concentrations in the plume are about 1.5-2 times higher than the observed TROPOMI values. Similarly, for the nearby coastal cities of Saudi Arabia (Dammam and Al-Jubail) and further away from the coast (Al-Hofuf, zone 3), the NO<sub>2</sub> concentration values for the model are much higher compared to the satellite observations. In the northern part of the domain, the coastal area of Saudi Arabia shows a more intense plume with concentrations two times higher in the satellite observations compared to the WRF-Chem model values (zone 2). The last noticeable plume is located over the western part of the domain, where the city of Riyadh is located (zone 1), with a wider and more intense plume in TROPOMI observations. We also note a secondary plume in TROPOMI data, south of the main one, which is not observed in the model.

In Fig. 11, we present a direct comparison of NO<sub>2</sub> concentrations between the satellite observations and the model, separated into four distinct zones (as described above). We selected these boxes as they include isolated plumes separable from other sources and estimated the sum of the 80th percentile concentrations for the tropospheric column (raw values - no Gaussian filtering) for each day of June and January 2021. The model-data correlations are larger for zone 1 despite the presence of a

secondary plume in this region (observed by TROPOMI but not by WRF-Chem) which suggests an overestimation of the modeled plume concentrations by the unique point source in Riyadh. For zone 2, the NO<sub>2</sub> concentrations were systematically underestimated by the model (1.5-2 times lower), whereas for zones 3 and 4 the WRF-Chem model overestimated the concentrations by a factor of 3-4 during both January and June 2021.

295

**Figure 11: Comparison of the total column NO<sub>2</sub> concentrations for the four zones (cf. Figure 10) for each day of January (a-c-e-g) and June (b-d-f-h) at 10:00 UTC, including the corresponding linear regression (dashed line; principle of least squares).**

In order to examine whether the model performances correspond to an overall underestimation or overestimation of the emissions, we applied the emissions scaling factors (in this case the slope of the linear fit) to the EDGAR emissions for the 4 zones separately and we summed the values for each, thus estimating the scaling factors for the sum. We know that this approach assumes linearity in the emission-to-concentration relationship, which is clearly not correct at the daily timescale. Sensitivity runs would be needed to define the impact of nonlinear chemical processes. However, the results presented in Table 2 suggest a large overestimation of the emissions, of about 2.5 times for both June and January, which is much larger than potential nonlinear reactions over the whole time period. Future studies should also include the nonlinear impacts of chemical reactions to quantify more accurately the NO<sub>2</sub> emissions, but our findings confirm the presence of large discrepancies between the EDGAR inventory (established for the year 2010) and the observed plumes at sub-national scale.

305

**Table 2: EDGAR NO<sub>x</sub> emissions per zone including applied emission scaling factor as occurred by the TROPOMI vs WRF plot slope.**

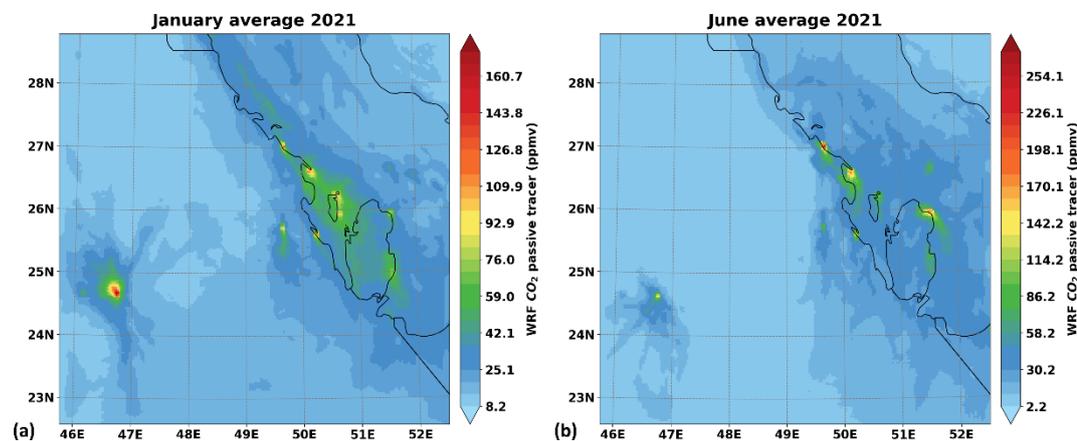

Total NO <sub>x</sub> emissions (monthly average)				
	EDGAR (June)	EDGAR (January)	EDGAR · slope Fig. 11 (June)	EDGAR · slope Fig. 11 (January)
	(moles cm <sup>-2</sup> )	(moles cm <sup>-2</sup> )	(moles cm <sup>-2</sup> )	(moles cm <sup>-2</sup> )
Zone 1	28562	28202	48841	32996
Zone 2	4203	4136	8112	8024
Zone 3	176173	153122	45805	47468
Zone 4	20868	24026	5843	10091

Scaling factor of sum	0.47	0.47		

310

### 3.3 Satellite and WRF-Chem enhancement ratios comparison

We now examine the performance regarding both NO<sub>2</sub> and CO<sub>2</sub> in plumes from large sources, more specifically the enhancement ratios ( $\delta\text{NO}_2:\delta\text{XCO}_2$ ) in plumes between the WRF-Chem simulation and the satellite observations. For this purpose we carried out simulations with CO<sub>2</sub> as a passive tracer for June and January 2021 using the EDGAR v 6.0 GHG anthropogenic emissions as introduced in Section 2.2. Fig. 12 shows the modeled tropospheric column XCO<sub>2</sub> plumes over the nested domain as simulated by the WRF-Chem model. The locations of the CO<sub>2</sub> plumes resemble the simulated NO<sub>2</sub> plumes (cf. Fig. 6) as we focus here on a region dominated by anthropogenic sources. Biogenic fluxes in desertic areas remain low compared to fossil fuel sources, especially over the Middle East where large point sources drive the observed XCO<sub>2</sub> gradients.

315

**Figure 12: Tropospheric column CO<sub>2</sub> concentrations for the WRF-Chem outputs monthly average for January 2021 (a) and June 2021 (b) at 10:00 UTC.**

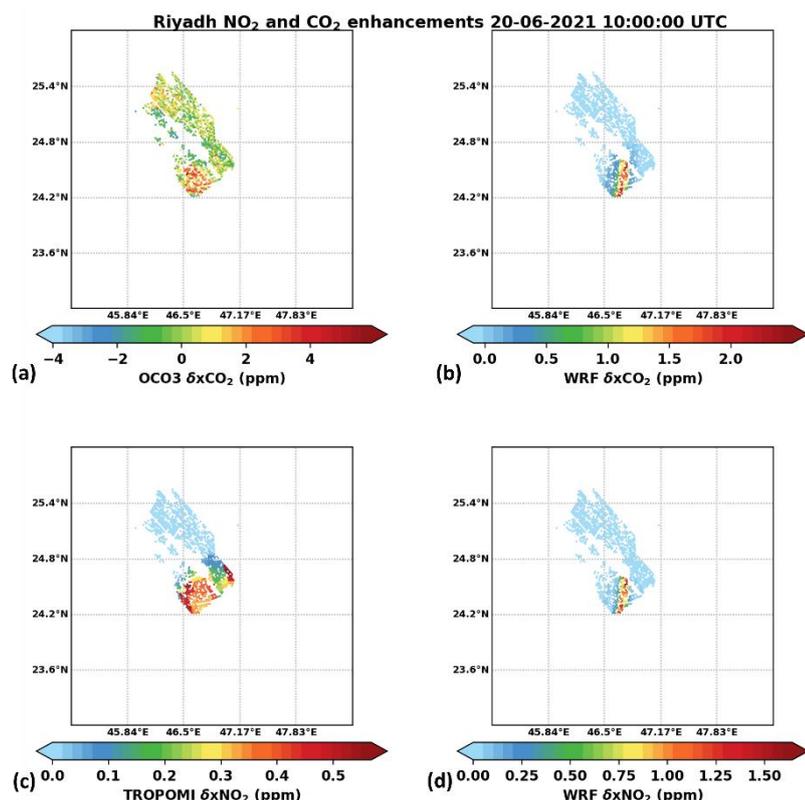

320

For the quantification of the enhancement ratios, we applied the method described in Macdonald et al. (2022) summarized here. The plume corresponds to the 80<sup>th</sup> percentile of the NO<sub>2</sub> concentration in each subregion (zones), consequently masked while the remaining field is considered as background. To avoid missing retrievals, the masked area was filled in using the nearest-neighbor interpolation technique and the resulting background field was subtracted from the plume values in order to obtain the enhancement fields  $\delta\text{NO}_2$  and  $\delta\text{XCO}_2$ . Fig. B1 and B2 show each step of the method for the TROPOMI and OCO-3 data respectively over the urban area of Riyadh. The TROPOMI satellite data were regridded to the model resolution and the units were converted from moles cm<sup>-2</sup> to ppb. The same method was applied to the WRF outputs for the same days.

Due to the scarcity of OCO-3 observations and the asynchronous sampling times of TROPOMI and OCO-3, we identified only 6 coincidental images over the time period, with 4 images for the urban area of Riyadh and 2 images for the urban area of Dammam. Fig. 13 shows two examples of observed and modeled  $\delta\text{NO}_2$  and  $\delta\text{XCO}_2$  plumes. Despite the plumes being correctly oriented in the WRF-Chem simulations, their widths appear lower than observed, for both TROPOMI and OCO-3. Considering that both gases are impacted by the same error, we suspect that transport model errors are responsible for the mismatch (wind speed, vertical mixing, or stability conditions) or the activity data used in EDGAR to map emissions are not diffused enough.

We decreased the potential impact of transport errors in our analysis by focusing on the integral over each plume, limiting the mislocation errors (due to incorrect wind speed and direction) that would affect a pixel-based analysis of the plumes. Here, the enhancement ratios were estimated based on the average value over the plume area.

340 **Figure 13: XCO<sub>2</sub> enhancements estimated from the OCO-3 observations (a), XCO<sub>2</sub> enhancements estimated from the WRF-Chem simulations (b), NO<sub>2</sub> enhancements estimated from the TROPOMI observations (c) and NO<sub>2</sub> enhancements estimated from the WRF-Chem simulations (full chemistry) (d) for the same coordinates over Riyadh on 20-06-2021 at 10:00 UTC**

The scatter plot of the WRF-Chem enhancement ratio values against the satellite (TROPOMI and OCO-3) is shown in Fig. 14. The linear regression of the enhancement ratios between WRF-Chem and the satellite concentrations shows a relatively good agreement (slope of 0.72; R<sup>2</sup> = 0.56) but the limited number of coincidental images in the observations limits the interpretation of our analysis. We note here that the 0.72 value of the slope is similar to enhancement ratios over large urban areas observed by MacDonald et al (2022) where the enhancement ratio values ranged from 0.5 ppb:ppm to 1.5 ppb:ppm and close to ratios over Mexico City with 0.55 ppb:ppm dominated by traffic and large industry sources (Lei et al., 2022). We also note one outlier with a high  $\delta XCO_2$  relative to the  $\delta NO_2$  enhancement (three times higher) corresponding to the 02/06/2021 case over the city of Dammam despite having fair weather conditions during that day. More interestingly, we note that the overestimation of  $\delta NO_2$  enhancements in WRF-Chem (cf. Table 2) also applies to  $\delta XCO_2$  values, resulting in a reasonable agreement in  $\delta NO_2 : \delta XCO_2$  ratios. Despite the limited number of available observations (due to limited sampling by OCO-3), this preliminary analysis confirms that potential biases in the EDGAR inventory affect both gases, confirming that a joint assimilation of these two species can potentially rely on existing gas-to-gas ratios from EDGAR. We conclude here that

345  
350

355 assimilating satellite observations of both NO<sub>2</sub> and CO<sub>2</sub> has the potential to improve emissions estimates from anthropogenic sources at sub-national scales.

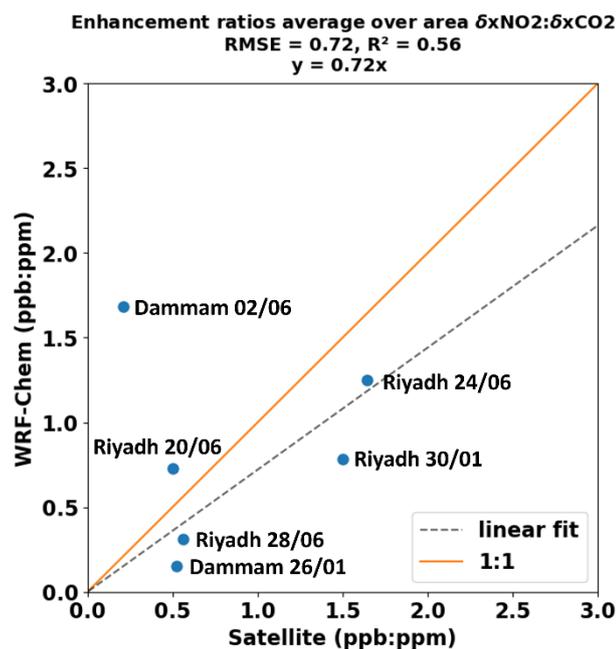

Figure 14: Comparison of the daily mean enhancement ratios ( $\delta NO_2:\delta XCO_2$ ) from the WRF-Chem simulations and the TROPOMI observations over the six days with available satellite observations

## Conclusions

360 As we demonstrated here, the abundance of satellite NO<sub>2</sub> concentrations from TROPOMI offers a unique set of observations for the quantification of NO<sub>2</sub> emissions and possibly for CO<sub>2</sub> emissions from large point sources or cities. An accurate representation of the NO<sub>2</sub> concentrations could lead to the quantification of the CO<sub>2</sub> emissions based on the known enhancement ratios  $\delta NO_2:\delta XCO_2$  from existing inventories. In this manner, we used WRF-Chem simulations in order to examine the chemistry impact of the model regarding NO<sub>x</sub>, to examine the performance of the EDGAR inventory, although it is only available for the year 2010, and to evaluate the model performances regarding the enhancement ratios. In particular, we selected the Middle East as our study area for multiple reasons (distinct plumes from power plants, low cloud cover, low vegetation and a nearly-constant albedo) which are ideal for satellite observations in general (here TROPOMI and OCO-3). We carried out simulations for June and January 2021 for three different cases: 1) full chemistry, 2) NO<sub>2</sub> and NO as passive tracers, and 3) CO<sub>2</sub> as a passive tracer.

370 The first step was the examination of the chemistry module performances (cbm-z scheme). We performed 10 days of WRF-Chem simulation for June 2021 with full chemistry applied and one with NO<sub>2</sub> and NO as tracers. By comparing the NO<sub>2</sub> and NO concentration with the distance from a point source over Riyadh, we showed that the full chemistry is required to achieve

realistic representation of NO<sub>2</sub> concentrations at short and long distances from the source. The NO<sub>2</sub> and NO concentrations are almost neglected around 40 km away from the source for a full chemistry run, whereas NO<sub>2</sub> concentrations remain significant  
375 even 60 km away for the tracers run. During the day, the mismatch in NO<sub>2</sub> concentrations between the full chemistry and the no-chemistry simulations reached up to 300% due to the absence of O<sub>3</sub> chemistry and despite the attribution of 90 % of the NO<sub>x</sub> emissions to NO<sub>2</sub> emissions (to compensate for the absence of NO<sub>2</sub>-to-NO conversion processes). During the night, when there is no incoming radiation, the NO<sub>2</sub> model-data mismatch reached up to 200 % near the source while decreasing further downwind (around 40 km away from the source).

380 Based on our full-chemistry configuration, we performed WRF-Chem simulations for the full months of January and June 2021. Our results confirmed the ability of the WRF-Chem model to represent the largest plumes over the Middle-East emitted by power plants. Furthermore, the locations of the plumes were in agreement with the satellite observations, despite transport model errors affecting the length and the width of the plumes. We defined four zones with large and distinct plumes in order to perform a spatial comparison with the TROPOMI satellite observations. The comparison revealed an underestimation of the  
385 NO<sub>2</sub> concentrations by the model of approximately 1.5-2 times for two zones and an overestimation of 3-4 times for the other two. By applying the specific scaling factors to the raw emissions for these four zones (linearity assumption) and summing them, we derived an overall overestimation by the EDGAR inventory equivalent to a factor of 2.5.

Finally, we simulated the CO<sub>2</sub> enhancements with WRF-Chem for June and January 2021. The estimation of the enhancement ratios showed values of approximately 0.7, which agrees with other relevant studies (e. g. Macdonald et al., 2022; Lei et al.,  
390 2022). Similar to the analysis of the NO<sub>2</sub> concentrations showing positive and negative corrections of the NO<sub>2</sub> emissions, the CO<sub>2</sub> model-data mismatches (OCO-3 retrievals) also showed similar mismatches. Despite the limited number of coincidental images of TROPOMI and OCO-3, we showed here that inconsistencies in sub-national CO<sub>2</sub> emissions in current global inventories might be corrected using NO<sub>2</sub> retrievals from TROPOMI. For future work, a detailed infrastructure map for the region could be taken into account to redistribute the anthropogenic emissions in a more realistic way, and the representation  
395 of nonlinear chemical processes to establish more accurately the relationship between emissions and concentrations. Future inverse studies of CO<sub>2</sub> emissions will assimilate jointly NO<sub>2</sub> and XCO<sub>2</sub> satellite observations, taking into account the full complexity of chemistry reactions affecting NO<sub>2</sub>, to produce monthly estimates over favorable regions (low cloud cover and reduced biogenic contribution).

### Author contribution

IC, TL and PC conceptualized this study. IC ran the WRF-Chem simulations, processed the data and analyzed the results for all the parts of the study with the help of JL, TC, GG and TL regarding the model set-up and the help of PK, YK, RL, TL and PC regarding the analysis of the results. IC, TL and PC wrote the original draft with contributions from AB for Section 3.1.  
420 All authors participated in the review and editing of the manuscript and agreed to this version.

### Competing interests

The authors declare that they have no conflict of interest.
